Abstract
This study investigates 3- to 5-year-old children’s sensitivity to lexical, intonational and gestural information in the comprehension of speaker uncertainty. Most previous studies on children’s understanding of speaker certainty and uncertainty across languages have focused on the comprehension of lexical markers, and little is known about the potential facilitation effects of intonational and gestural features in this process. A total of 102 3- to 5-year-old Catalan-speaking children participated in a comprehension task which involved the detection of uncertainty in materials that combined lexical, intonational and gestural markers. In a between-subjects design, the children were either administered the lexical condition (where they were exposed to lexical and gestural cues to uncertainty) or the intonation condition (where they were exposed to intonational and gestural cues to uncertainty). Within each condition, three different presentation formats were used (audio-only, visual-only and audio-visual) in a within-subjects design. The results indicated that all the children performed better overall when they had gestural cues present. Furthermore, in comparison with the...
older group, the younger group was more sensitive to intonational marking of speaker uncertainty than to lexical marking. This evidence suggests that the intonational and gestural features of communicative interactions may act as bootstrapping mechanisms in early pragmatic development.

Belief states, epistemic stance, gesture, intonation, language acquisition, pragmatic development, prosodic development, uncertainty

**Introduction**

In everyday conversation, speakers are able to rapidly combine multimodal information during utterance comprehension, including verbal content, prosody and gesture. In particular, in successful social interactions the detection of belief states such as uncertainty (or incredulity, surprise, etc.) is especially important in order to understand the other person’s epistemic stance. Epistemic stance refers to the degree of commitment or certainty the speaker has in his or her statements. When inferring uncertainty, listeners can use various cues (depending on the language) such as lexical epistemic markers, morphological marking, gestures such as head nods and facial expressions, or prosodic features such as delays and final rising intonation (e.g. Swerts & Krahmer, 2005 or Borràs-Comes, Roseano, Vanrell, Chen, & Prieto, 2011, for a review). Typical lexical markers in English, for instance, are mental state verbs (such as think) and epistemic modal expressions (such as maybe). These lexical items convey information about the epistemic stance of individuals. In many languages intonation plays a key role in shaping the pragmatic meaning of utterances and can encode epistemic and evidential information (see Barth-Weingarten, Dehé, & Wichmann, 2009; Prieto, 2015, for a review of the literature on the prosody–pragmatics interface). Gesture patterns can also play an important part in conveying epistemic information. For example, Swerts and Krahmer (2005) investigated the role of audio-visual prosody for signalling and detecting epistemic information in question answering. The study showed that there are well-defined visual cues that demarcate a speaker’s feeling of knowing and that listeners are more capable of estimating another person’s knowledge on the basis of visual and auditory information combined than just auditory input alone.

In the study of language development, one of the interesting questions is how and when children develop the ability to recognise an interlocutor’s epistemic stance and feeling of knowing. To date, most research has concentrated on children’s acquisition of lexical markers of belief states. Moore, Bryant, and Furrow’s (1989) classical study tested 3- to 8-year-old children in an experimental setting where children had to find an object in one of two boxes as they listened to verbal cues from two different puppets telling them about the place where the object was hidden. Each utterance contained a marker with a different degree of certainty, signposting one or the other box as the location of the hidden object, such as I know it’s in the red box or I think it’s in the blue box. The results showed that children aged 4 and above were able to find the hidden object
based on what they heard but 3-year-olds were not. Furthermore, Moore, Pure, and Furrow (1990) also showed that the understanding of modal expressions such as might strongly correlates with the understanding of mental verbs such as think. Likewise, Noveck, Ho, and Sera (1996) tested 5- to 9-year-old children’s understanding of epistemic modals by contrasting has to with might, etc., and showed that (a) their understanding of modal expressions develops gradually over time; and (b) by 9 years of age children show an adult-like understanding of these modal expressions. There is one exception, though, by Moore, Harris, and Patriquin (1993), who compared children’s (3 to 6 years old) comprehension of mental state lexicon to their comprehension of mental state prosody. Children had to listen to contrasting pairs of statements by two puppets and guess the location of a hidden object. Each statement pair either differed with respect to the mental state verbs know vs think or think vs guess – or with respect to terminal pitch contour – falling or rising. While 3-year-olds were not able to use either lexicon or prosody to detect where the object was, 4-year-olds started to do so significantly in the know vs think and falling vs rising contrast conditions. Furthermore, the think vs guess condition was much harder even for the 5-year-old children, compared to the know vs think condition. In a follow-up experiment with 3- to 5-year-old children, the conditions were presented as either matched or mismatched. While in the matched condition lexical items of certainty went together with falling intonation and lexical items of uncertainty were matched with rising intonation, in the mismatched condition the opposite was applied. While 4-year-olds performed significantly above chance when know vs think was matched with the corresponding prosodic cue, they did not show any significant difference between matched vs mismatched trials. This time 5-year-olds performed much better on the think vs guess distinction in the matching condition. But, interestingly, 5-year-old children performed much worse in the mismatched condition, showing a certain awareness of prosodic and lexical integration when speaker (un)certainty is expressed. The authors suggested that prosodic and lexical cues to speaker certainty start to be used around the same time by children. Yet, the authors propose that lexical cues to a speaker’s belief state initially seem to be more dominant, with prosody playing a secondary role, modulating the effects of the lexical cues. More recent studies have investigated the acquisition of belief states, focusing on other languages such as Korean (Choi, 1995; Papafragou, Li, Choi, & Han, 2007), Cantonese (Lee & Law, 2001; Tardif, Wellman, & Cheung, 2004), Turkish and Puerto Rican Spanish (Shatz, Diesendruck, Martínez-Beck, & Akar, 2003), Japanese (Matsui, Yamamoto, & McCagg, 2006), and Japanese and German (Matsui, Rakoczy, Miura, & Tomasello, 2009), yet with a sole focus on lexically encoded mental state information.

There seems to be a general consensus that it is not until age 4 that children are capable of identifying the meaning of modal expressions of uncertainty. Yet Matsui et al. (2006) investigated children’s understanding of knowledge states in Japanese, where uncertainty can be encoded through both epistemic particles (yo = speaker certainty and kana = speaker uncertainty) and mental state verbs (such as shitteru = know and omou = think). They found that 3-year-old Japanese children already comprehended a speaker’s knowledge state, but only when it was conveyed by particles. By contrast, at that age their understanding of mental state verbs was still quite poor (see Matsui, 2014, for a detailed overview of children’s understanding of epistemicity and evidentiality).
Studies of children’s pragmatic development have claimed to take into account gestural cues in the study of communication and language development (e.g., Furman, Kuntay, & Ozyurek, 2014; Guidetti, 2005; Guidetti, & Nicoladis, 2008; Iverson & Goldin-Meadow, 1998; McNeill, 1998; O’Neill, Bard, Linnell, & Fluck, 2005). There is a growing consensus that gestures act as bootstrapping devices in language development (Butcher & Goldin-Meadow, 2000; Kelly, 2001; McNeill, Cassell, & McCullough, 1994). With respect to the acquisition of belief states, some studies seem to suggest an earlier development of uncertainty understanding based on non-linguistic cues. For example, some studies have shown that 3- and 4-year-old children are capable of deciding who to believe based on visual signs of reliability or inference (Koenig, Clément, & Harris, 2004; Koenig & Harris, 2005; Robinson, Mitchell, & Nye, 1995; Robinson & Whitcombe, 2003; Sabbagh & Baldwin, 2001; Whitcombe & Robinson, 2000). There have been two studies that focused on older children (8 to 11 years old) which have investigated the development of their perception and production of facial gestures as cues to uncertainty (Krahmer & Swerts, 2005; Visser, Krahmer, & Swerts, 2014). More basic forms of epistemic stance comprehension are also found early on in infancy. It has been shown that 12-month-olds are able to distinguish between knowledgeable and ignorant partners (Liszkowski, Carpenter, & Tomasello, 2008). The study explored the ability of 12-month-old infants to point appropriately at an object in order to provide uninformed people with information. To signal ignorance, the experimenter raised his/her hands with the palms upturned. Their results showed that infants pointed more often to an object which the adult had (presumably) not seen fall down and thus needed help to find than an object which the adult had seen fall down and thus could find unassisted.

All these studies suggest that children achieve important communicative milestones initially in the realm of gesture before they do so in speech, and gestures can therefore be seen as helping children to access meaning (e.g., Goldin-Meadow, 2007). While the role of prosody as a syntactic bootstrapper has been highlighted in language acquisition research, that is certain types of prosodic features guide children’s initial acquisition of word order and syntactic structure (e.g. those related to constituent or prosodic phrasing; for a conceptualisation see Hirsh-Pasek, Tucker, & Golinkoff, 1996; see also Christophe, Nespor, Guasti, & Van Ooyen, 2003), so far very little is known about the role of prosody in early pragmatic development and whether it might have a possible bootstrapping effect on the comprehension of pragmatic meaning.

Recent studies on the prosody–pragmatics interface have shown that 12-month-old infants use prosody (together with pointing gestures) to comprehend an adult’s basic communicative intentions like expressive, imperative and informative attention-directing actions (Esteve-Gibert, Prieto, & Liszkowski, 2017), and that 14-month-old infants can use prosody to distinguish between intentional and non-intentional acts (Sakkalou & Gattis, 2012). Also, research has shown that infants as young as 2 display a basic inventory of target-like intonation contours with an adult-like intentional meaning (e.g., Chen & Fikkert, 2007; Frota, Cruz, Matos, & Vigário, 2016; Prieto, Estrella, Thorson, & Vanrell, 2012). Thus, independent evidence coming from studies investigating the acquisition of pragmatic intonation seems to suggest an initial role for prosody as a bootstrapping mechanism in the early stages of the understanding of pragmatic meaning.
While prosody is a very prominent cue in infancy, studies testing preschool and school-age children’s understanding of prosody have yielded conflicting results. On the one hand, research on children’s sensitivity to pitch as a cue to emotions has shown that the adult-like ability to judge a speaker’s emotional state based on vocal affect is mastered only at 4 years, after children have acquired the lexical semantic meaning of the four basic emotions (happiness, sadness, anger and fear), which happens around age 3 (Morton & Trehub, 2001; Nelson & Russell, 2011; Quam & Swingley, 2012). Yet, when there are cues in competition regarding the relevant emotion conveyed via either the lexical meaning of a sentence (Morton & Trehub, 2001; Waxer & Morton, 2011) or the situational context (Aguert, Laval, Lacroix, Gil, & Le Bigot, 2013; Aguert, Laval, Le Bigot, & Bernicot, 2010), the success of preschoolers at identifying vocal affect seems compromised. For example, if someone utters ‘It’s Christmas time’ with a sad prosody, adults will rely on the prosody and judge the speaker to be sad, whereas 6-year-old children will say the speaker is happy. By the same token, Vernice and Guasti (2014) showed that before age 5 children are not able to use prosodic cues in order to decide which referent to mention next. While all these studies hint at a surprisingly late acquisition of certain prosodic cues at the sentence level, a very recent study by Berman, Chambers, and Graham (2016) discovered that when a more implicit methodology such as eye-tracking is used, young children already at age 3 show themselves able to link speech bearing different acoustic cues to emotion. Unfortunately, overall these studies lack a description of the acoustic characterisation of the prosodic differences between the different emotions described, which makes it hard to track which prosodic cues children learn to attend to (with the exception of Quam & Swingley, 2012). Furthermore, these prosodic cues to emotion might only be subtle cues that do not involve a real change in pragmatic intonation patterns.

On the other hand, however, hardly any research has focused on when and how children understand more complex pragmatic meanings such as epistemicity encoded through prosody and/or gestures. A recent exception is Armstrong (2012, 2014), which focused on children’s comprehension of intonationally encoded disbelief in polar questions in Puerto Rican Spanish. Particularly relevant for the current study is the study by Armstrong, Esteve-Gibert, and Prieto (2014), which investigated 3- to 5-year-old understanding of disbelief (or incredulity) through three different modalities: visual-only (facial gesture cues), audio-only (intonation) and audio-visual (facial gestures and intonation). The children were exposed to short discourse reactions such as *Una balena?!* (‘A whale?!’) produced with either incredulous or credulous intonation, and they had to decide between the two meanings. The results showed that 3-year-old children performed the worst on the audio-only task, while 4-year-olds performed better, but still showed great variability. Also, a great deal of variability was observed for younger children that received the audio-visual condition, arguably because it was difficult for some of them to integrate the two cues. By contrast, 3- and 4-year-olds performed much better in the visual-only condition compared to the other two conditions. Furthermore, 5-year-old children performed equally well in the audio-only condition. The authors suggest that facial gestures seem to provide children with scaffolding for the detection of speaker disbelief. However, one aspect that this study could not explore was the children’s sensitivity to prosodic and gestural features relative to lexical cues, which were not included in the study.
The main purpose of the current study is to assess the relative roles of lexical, intona-
tional and gestural cues in preschoolers’ understanding of uncertainty and to test the
potential bootstrapping role of gestures and intonation in its development. Specifically,
we are interested in whether children (1) use gestures as a bootstrapping device in the
comprehension of uncertainty and (2) recognise uncertainty more easily through lexical
or intonational epistemic markers. To address these questions, we asked 3- to 5-year-olds
to select the uncertainty stimuli in a forced-choice task.

A modified version of Armstrong et al.’s (2014) incredulity comprehension task was
used here in which children had to decide which speaker was uncertain about something.
Importantly, the two experimental conditions (uncertainty/certainty) were tested using
stimuli presented in either visual-only, audio-only, or audio-visual modality.

In line with previous studies on the facilitator role of gestures in general (e.g. Furman
et al., 2014; Guidetti, 2005; Iverson & Goldin-Meadow, 1998; McNeill, 1998; O’Neill
et al., 2005) and in particular in disbelief understanding (Armstrong et al., 2014), we
expected that the presence of visual information would bootstrap children’s understand-
ing of belief state. Furthermore, contrary to previous studies on the late acquisition of
meaning encoded through prosody, it was our position that children younger than 4 years
would be sensitive first to intonational cues to uncertainty, then to lexical ones. The
results would therefore be important to further our understanding of how pragmatic com-
munication skills develop in children and the role intonation and gesture play in this
development.

Methods

Participants

A total of 102 3- to 5-year-old children participated in the experiment. Children were
divided into a younger group (N = 51, mean age = 3 years and 9 months, SD = 5.50) and
an older group (N = 51, mean age = 5 years and 2 months, SD = 5.27). All the participants
were preschoolers at three Catalan public schools located in the Barcelona area. In these
schools, the main language of instruction is Catalan.1 Parents were informed about the
experiment’s goal and signed a participation consent form. Furthermore, language expo-
sure questionnaires (based on Bosch & Sebastián-Gallés, 2001) were administered to the
caregivers in order to ensure that the participating children were predominantly exposed
to Catalan (as opposed to Spanish) on a daily basis (mean percentage of overall exposure
to Catalan: 87%, SD = 12.0).

Design

The target materials were video recorded by taking into consideration the results of a
general knowledge quiz which was constructed to elicit the spontaneous use of utter-
ances conveying different degrees of certainty in Catalan, based on Krahmer and Swerts
(2005). We analysed the lexical, gestural and prosodic expressions of certainty in a
total of 180 answers (12 questions × 15 participants). Results showed that participants
mainly used two different types of intonation patterns, depending on the certainty condi-
tion. In the certain condition they universally used a falling pitch contour L* L% (100%
of the cases) and in the uncertain condition they used two variants of a rising pitch contour, L* H% and L+H* H% (which covered 25% of the cases). Furthermore, participants used lexical items (potser ‘perhaps’, crec que ‘I think’, etc.) in 25% of the cases, which went together with a falling intonation (L* L%) when expressing uncertainty (the remaining 50% belonged to lower degrees of uncertainty). Finally, participants produced a head nod when being certain, and a varied group of gestures (e.g. diverted gaze, low/high gaze, raised or furrowed eyebrows, squinted eyes, head tilt) when being very uncertain.

Taking these findings into account, three adult Catalan speakers were videotaped while producing a total of 12 target utterances each (6 trials × 2 epistemic marking conditions; see Appendix), resulting in a grand total of 36 target stimuli (3 speakers × 12 utterances). The epistemic marking conditions consisted of utterances expressing certainty/uncertainty through both lexical and gestural markers (this will henceforth be referred to as the lexical condition), and utterances expressing certainty/uncertainty through only intonation and gestural markers (henceforth the intonation condition). A fourth Catalan speaker was recorded for the familiarisation trial.

For the lexical condition we used the following lexical epistemic markers: a common adverb signalling uncertainty in Catalan (potser ‘maybe’), and a very common epistemic construction which signals certainty (segur que ‘[I am] certain that’). Thus, the certainty stimuli consisted of a noun phrase preceded by the adverb segur que ‘[I am] certain that’ (e.g. Segur que el tomàquet ‘[I am] certain that [it’s] the tomato’) and accompanied by a head nod gesture suggesting certainty (Figure 1, left-hand panels). The uncertainty stimuli consisted of a noun phrase preceded by the adverb potser ‘maybe’ (e.g. Potser el tomàquet ‘Maybe [it’s] the tomato’) and accompanied by gestures suggesting
uncertainty (squinted eyes, raised eyebrows, head tilt) (Figure 1, right-hand panels). Crucially, both certainty and uncertainty utterances were produced with the same intonation contour (L* H% associated with the adverb plus final falling intonation, L* L%).

For the intonation condition, the certainty stimuli (e.g. El tomàquet ‘The tomato’) were produced with a falling intonation contour (L* L%) and accompanied by a head nod gesture suggesting certainty (Figure 2, left-hand panels). The uncertainty stimuli (e.g. El tomàquet? ‘The tomato?’) were produced with a rising intonation contour (L* H%) and gestures suggestive of uncertainty (squinted eyes, raised eyebrows, head tilt) (Figure 2, right-hand panels). Crucially, in the intonation condition the utterance contained no lexical information such as epistemic adverbs which would help to distinguish certain from uncertain stimuli.

Each epistemic marking condition was presented in three different modalities: audio-only, visual-only and audio-visual. For the audio-only trials, the audio track was played to subjects and the visual information reduced to a minimum by displaying two still photos of the speakers with a neutral facial expression. For the visual-only trials, the audio track was removed from the original audio-visual stimuli so that only the visual information was available to subjects. For the audio-visual trials, both the audio track and the accompanying video images were presented.

Table 1 summarises how the combination of lexical, intonational and gestural cues differed across the epistemic marking conditions (lexical condition vs intonation condition) and modalities of presentation (audio-only, visual-only, or audio-visual). This design was intended to allow us to assess the role of the visual cues with respect to the speech cues (be they intonational or lexical cues) in (un)certainty detection.

The semantic appropriateness of the stimuli selected was controlled for by running an experiment with the online survey platform SurveyGizmo. Sixty Catalan-speaking adults

(30 respondents x 2 epistemic marking conditions) were asked to rate each of the 9 experimental stimuli sets (including both uncertainty and certainty stimuli), yielding a total of 540 tokens. Out of these 540, only two elicited contradictory certainty ratings by respondents. These two stimuli were subsequently re-recorded, and further testing yielded consistent ratings.

Set-up of the task

This task is an adaptation of the task used in Armstrong et al. (2014). A PowerPoint presentation depicted the story of two twins travelling on a train with their friend Barbara, who plays a game with them to help make the journey pass more quickly. The game consists of her asking the twins if they know about her favourite things. For example, Barbara asks them, ‘What is my favourite vegetable?’ The answer is then revealed visually as a tomato in a thought bubble (Figure 3, left image), which the experimenter points out to the child. Previous research has shown that 3-year-olds understand thought bubbles as representations of mental contents (Wellman, Hollander, & Schult, 1996).

During the experiment, the child subject was seated in a position to view the screen as a researcher talked and operated the PowerPoint slide show. Once the twins and Barbara had been introduced and the basic guessing game scenario described, the researcher told the child that for each question there was one twin who was sure of the right answer and one who was not, and that the child had to point to the uncertain twin. The child’s response was regarded as ‘correct’ if s/he pointed to the twin who expressed uncertainty (Figure 3, right image).

Procedure

The children were tested individually in a quiet room at each of the three participating schools. The researcher, a male Catalan-speaking adult (the third author of this article), was seated beside the child in a room at the child’s school, so that both faced the computer
screen. The children were administered either the lexical or intonation condition (between-subjects), each containing 3 audio-only, 3 visual-only and 3 audio-visual trials (within-subjects) in a randomised order. Prior to performing the comprehension task, each participant first went through a familiarisation trial to make sure that they understood what they were supposed to do. They then performed a total of 9 test trials in two counterbalanced orders, either first 3 audio-only, then 3 visual-only and finally 3 audio-visual, or first 3 visual-only, then 3 audio-only and finally 3 audio-visual. After each set of 3 trials, in order to prepare the child for the change in modality, s/he was shown a filler slide depicting either a photo of an ear (signalling audio-only), an eye (visual-only), or both (audio-visual). In total the procedure lasted at most 10 minutes.

Results

A total of 918 children’s responses were obtained from the comprehension task (9 responses × 102 children) and then analysed through a Generalised Linear Mixed Model (GLMM) using IBM SPSS Statistics 21. The dependent variable was ‘child’s performance’, a numerical measure obtained by calculating the mean proportion of correct to incorrect responses. The fixed factors were epistemic marking condition (two levels: intonation condition, lexical condition), modality of presentation (three levels: audio-only, visual-only, audio-visual), age group (two levels: younger group, older group), and all their possible interactions. The random factor was participants.

Figure 4 shows the mean proportion of correct responses broken down by epistemic marking condition (intonation and lexical) and modality condition (audio-only, visual-only and audio-visual) for the two age groups (younger and older) in the sample. Table 2 displays the relevant means and standard deviation for each epistemic marking condition and modality of presentation in both age groups.

The GLMM analysis revealed a main effect of age group, $F(1,294) = 21.215, p < .001$, with older children performing significantly better than younger children, and a main effect of epistemic marking condition, $F(1,294) = 10.064, p < .01$, indicating that when children were presented with the intonation condition they performed significantly better than when they were presented with the lexical condition.
There was also a main effect of presentation modality, $F(2,294) = 20.314, p < .001$. Pairwise contrasts showed that when children were presented with visual modalities (visual-only and audio-visual), they performed significantly better than when presented with the audio-only modality ($p < .001$), with no difference between the two visual
modalities \( (p = .052) \). Having the visual information present clearly helps the children to detect uncertainty better and thus confirms our first hypothesis that gesture has a bootstrapping effect on the child’s comprehension of pragmatic meaning.

The model also reported a significant interaction between age group and epistemic marking condition, \( F(1,294) = 7.751, p < .01 \). Pairwise comparisons showed that only the younger children performed significantly better in the intonation condition as compared to the lexical condition \( (p < .001) \). All the other main effects and possible interactions were not significantly different. This confirms our second hypothesis, namely that younger children are able to detect epistemic meaning first through intonational cues before doing so through lexical cues.

Discussion and conclusions

The aim of this study was to investigate the role of intonational, lexical and gestural cues in the early development of epistemic understanding. Overall, the results of the comprehension task with 102 3- to 5-year-olds showed that children make great strides in their comprehension of uncertainty between the ages of 3 and 5, as seen by the fact that children in the older age group performed significantly better than those in the younger age group. These results are in line with previous studies that found that lexical understanding of uncertainty is achieved between the ages of 4 and 5. It is not surprising that younger children did not perform well in the lexical condition, since it has been documented across languages that children acquire the difference between different degrees of speaker certainty expressed through modal auxiliaries only around age 4 (e.g. Moore et al., 1990).

Yet the main question addressed by this study was whether younger preschool children attain epistemic understanding earlier through gestural and intonational features as compared with lexical features, and thus whether these features give them their first understanding of others’ belief states. In the present study, by comparing three modalities of communication (audio-only, visual-only and audio-visual), it was possible to investigate the relative contributions of gesture, lexical and intonational cues to children’s pragmatic comprehension. Our results showed that both younger and older children perform significantly better in the visual-only and the audio-visual modality than in the audio-only modality. These findings are comparable with those of Armstrong et al. (2014), where facial gestures also seemed to scaffold children’s performance in detecting belief state meaning (i.e. incredulity). By the same token, they are compatible with the growing consensus that gestures act as bootstrapping devices in language development in general (e.g. Butcher & Goldin-Meadow, 2000; Kelly, 2001; McNeill et al., 1994).

With respect to the contribution of intonation, the novelty of our study lies in the fact that our experimental methodology allowed for a direct comparison between the children’s sensitivity to intonational vs lexical cues to uncertainty. Crucially, our results showed that 3-year-old children were more sensitive to salient intonational cues to uncertainty (in our case, a rising intonation pattern L* H%) than to lexical cues to uncertainty, regardless of whether visual information was also available or not. This result contradicts previously found results by Moore et al. (1993), who regarded prosody as playing a secondary role in children’s acquisition of belief state meanings. Furthermore, our results
show that 4- and 5-year-olds, by contrast, performed equally well in the audio modality in both epistemic marking conditions, showing that they have acquired an understanding of lexical cues by this age.

These results also seem to point in a different direction than previous studies on children’s development of emotional prosody (Morton & Trehub, 2001; Nelson & Russell, 2011; Quam & Swingley, 2012), which have found that children’s ability to match the auditory cues to the four basic emotions (happiness, sadness, anger and fear) seems to appear after children have acquired the lexical-semantic meaning of these emotions. Furthermore, when 5-year-old children are confronted with contrasting lexical cues or additional neutral situational cues juxtaposed on prosodic cues, they rely for their judgements on the lexical or situational cues rather than basing their judgement on the vocal cues encoding emotions. Thus, overall, this research would lead to the interpretation that prosodic cues do not seem to be prominent in the preschool years in leading children to detect emotional/attitudinal meaning in speech and that children rather use other cues to guide them (Aguert et al., 2010, 2013; Nelson & Russell, 2011; Waxer & Morton, 2011).

However, these studies deal with emotional prosodic cues (mostly pitch cues of contrasting pitch range) for inferring another person’s emotional state, and these are weak prosodic cues not involving distinct pragmatic intonation patterns (Aguert et al., 2013; Quam & Swingley, 2012; Waxer & Morton, 2011). By contrast, our study has shown that 3-year-old children are sensitive to intonational contrasts involving final rise (H%) vs final fall (L%) distinctions for inferring speaker belief. In our data, developmental changes in children’s comprehension of belief states become evident first in intonation (and in gesture) and only later in lexical marking. Thus our results seem to suggest that, regardless of the fact that mastering emotional prosody can appear later in development, intonational linguistic contrasts indicating complex pragmatic functions are probably mastered well before children acquire the lexical epistemic markers. Similar to the hypothesis of early prosodic bootstrapping, we contend that not only does prosody play a crucial role in the early acquisition of language by helping children to decode syntactic structure but that in later stages of development prosody and gesture both exert a different type of bootstrapping effect, namely, they facilitate the acquisition of pragmatic meaning. While our study shows that young children are able to understand epistemic meaning encoded through intonational and gestural cues earlier than through lexical cues, further steps need to be taken to prove whether prosodic and gestural abilities are predictive of later lexical acquisition, that is, whether there exists a direct correlation between early understanding of prosodic and gestural cues and the subsequently following lexical comprehension.

To summarise, the results of the current study suggest that not only gesture but also pragmatic prosodic patterns act as an integral part of the language-learning process at the intermediate stages of language development. These prosodic and gestural features can probably be claimed to act as bootstrapping devices in which children ground their early pragmatic development. We thus argue that early sensitivity to and acquisition of prosody and gesture patterns should receive more attention in developmental research in order for us to gain a more complete picture of children’s pragmatic development.
Acknowledgments

We would like to thank the staff at the Escola Sant Martí, Escola La Farigola del Clot, and Escola Pública Dr. Estalella Graells for granting us access to and organizing the meetings with preschoolers. We also would like to thank the children and their families for their participation in the experiment. Furthermore, many thanks to Joan Borràs-Comes, Alba Ayneto, Laia Mayol, and Santiago González for participating in the recordings of the experimental materials, and to the participants in the general knowledge quiz (who were all students and researchers at the UPF). Also thanks to Joan Borràs-Comes again for assistance with the statistical analyses. Finally we are grateful to Marc Swerts, Martine Grice, Judy Reilly and Meghan Armstrong for thoughtful ideas and comments at different international meetings.

Declaration of conflicting interests

The author(s) declared no potential conflicts of interest with respect to the research, authorship, and/or publication of this article.

Funding

The author(s) disclosed receipt of the following financial support for the research, authorship, and/or publication of this article: This research has been funded by a grant awarded by the Spanish Ministry of Science and Innovation (FFI2015-66533 BFU2012-31995 “Intonational and gestural meaning in language”), and by a grant awarded by the Generalitat de Catalunya (2014SGR-925) to the Prosodic Studies Group.

Notes

1. Escola Sant Martí in Arenys de Munt, Escola La Farigola del Clot in Barcelona and Escola Pública Dr. Estalella Graells in Vilafranca del Penedès.
2. Catalan, like other Romance languages, uses a set of epistemic markers and morphosyntactic resources to mark epistemic commitment such as epistemic adverbs (e.g. potser ‘perhaps’), conditional forms (e.g. vindria ‘I would come’), verbal tense and subjective mood (e.g. dubto que vingui ‘I doubt he’d come-subjunctive’), etc.
3. The two forms typically appear in sentence-initial position and thus in an especially prominent position for children to acquire them (for more information about epistemic and evidential marking in Catalan, see González, Borràs-Comes, Roseano, & Prieto, 2014).
